Locators

In Terminology, we described briefly how the Ice run time uses an intermediary, known as a *location service*, to convert the symbolic information in an indirect proxy into an endpoint that it can use to communicate with a server. This section expands on that introduction to explain in more detail how the Ice run time interacts with a location service. You can create your own location service or you can use IceGrid, which is an implementation of a location service and provides many other useful features as well. Describing how to implement a location service is outside the scope of this manual.

A locator is an Ice object that is implemented by a location service. A locator object must support the Slice interface Ice::Locator, which defines operations that satisfy the location requirements of the Ice run time. Applications do not normally use these operations directly, but the locator object may support an implementation-specific interface derived from Ice::Locator that provides additional functionality. For example, IceGrid's locator object provides access to an IceGrid::Query object so that applications can perform more sophisticated queries.
